Abstract

A major obstacle to widespread acceptance of formal verification is the difficulty in using the tools effectively. Although learning the basic syntax and operation of a formal verification tool may be easy, expert users are often able to accomplish a verification task while a novice user encounters time-out or space-out attempting the same task. In this thesis, we assert that often a novice user will model a system in a different manner — semantically equivalent, but less efficient for the verification tool — than an expert user would, that some of these inefficient modeling choices can be easily detected at the source-code level, and that a robust verification tool should identify these inefficiencies and optimize them, thereby helping to close the gap between novice and expert users. To test our hypothesis, we propose some possible optimizations for the Murφ verification system, implement one of these, and compare the results on a variety of examples written by both experts and novices (the Murφ distribution examples, a set of cache coherence protocol models, and a portion of the IEEE 1394 Firewire protocol). The results support our assertion — a nontrivial fraction of the Murφ models written by novice users were significantly accelerated by the single optimization. Our findings strongly support further research in this area.

Acknowledgments

This work would not have been possible without extensive support and encouragement from Alan Hu.

I owe many individuals a debt of gratitude for helping me to find this path, and for making the journey more enjoyable. Most important of these were Wendy Belluomini, who provided invaluable advice and guidance, and H. Peter Hofstee, who taught me many valuable lessons and was always generous in his support.

Lastly, I might have missed the boat completely, had Tom Zavisca not twisted my arm at the right time.

To my parents, for their endless patience and support.

Chapter 1

Introduction

A major obstacle to widespread acceptance of formal verification is the difficulty in using the tools effectively. Ideally, the tools should be accessible to non-experts, so that formal verification can be used as just another technique to aid design and verification. While some effort learning a tool can be expected, the user must not be expected to have a deep understanding of the specific algorithms and heuristics used by the tool. In reality, the situation is markedly different. Although the syntax and basic operation of formal verification tools might be easy to learn, there is usually considerable subtlety in using the tools effectively on large problems. Expert users with a deep understanding of a tool are able to achieve impressive results; novice users are all too frequently frustrated by exploding memory and CPU time usage.

1.1 Motivation

A key difference between novice and expert is that the expert has a detailed understanding of the algorithms and heuristics used by a tool and can use that understanding to choose an efficient way to present the verification problem to the tool.

When applying formal verification, many choices must be made: how to model parts of the system, which parts of a system to abstract, how to perform that abstraction, and so forth. Differing choices can result in an equivalent verification problem, but some choices will be more or less efficient than others for the particular verification tool. When the novice has the chance to consult with the expert, advice often takes the form, "Don't model it like that; do this instead. Otherwise, ...," where the consequence reflects detailed knowledge of the tool: the BDD will have to represent all permutations, the state space will lose symmetry, the reduction heuristic will not work, and so forth. This situation is clearly undesirable; the novice is forced to become an expert on and adapt to the idiosyncrasies of the tool. Even for the expert, being forced to adapt to the tool can be suboptimal, since the description style that most clearly matches the verification problem might not be the style that best suits the verification tool. Also, over time the algorithms used by the tool may change, forcing the expert to rewrite models in order to take advantage of improvements to the tool.

Rather than forcing the user to adapt to the tool, the tool should adapt to the user. A robust, practical verification tool should help close the gap between novice and expert, allowing the novice to get useful results without a lengthy learning curve. For novice and expert alike, the tool should free the user to match the description to the problem being verified, rather than to specific quirks of the verification tool.

We hypothesize that often a novice will model a system differently (less efficiently for the tool) than an expert would, that many of these inefficient modeling choices can be easily detected in the source code of the model description, and that the tool should be able to optimize away these differences.

1.2 Project

To test our hypothesis, we consider a small set of source-level transformations with a specific tool. We have chosen the Murφ verification system [6, 5] as the target for our test. The choice of Murφ is fairly arbitrary — our ideas should apply in general, although specific optimizations, obviously, apply only to verification tools with similar features. We will give a brief overview of Murφ in Chapter 2, followed by a sampling of related work.

In Chapter 3, we will propose three possible Murφ source-level transformations which may improve models written by novice users. The first, ruleset rearrangement, eliminates redundant rule firings. These extra rule firings can occur when users group rules without considering the implementation details of how Murφ evaluates rules. The second, scalarset identification, is an automatic means of finding a particular type of symmetry. Exploiting symmetry can significantly reduce both time and space requirements, but novices may not understand how symmetry works or the importance of exploiting it. The last transformation, variable clearing, evaluates data dependencies to find when variables are no longer relevant. Failing to clear variables when they become irrelevant causes creation of redundant states, increasing time and space requirements. As with the other transformations, novices are unlikely to grasp the impact of variable clearing on the verification of their model.

We have implemented the first proposed transformation, ruleset rearrangement, as a modification of Murφ 3.1. We chose not to implement scalarset identification and automatic variable clearing, because of structural problems in the Murφ compiler. In Chapter 4 we will describe our implementation and the details of those problems.

To test the effectiveness of our transformation, we apply it to three sets of examples, including models written by both experts and novices. The results of our experiments, which we will present in Chapter 5, support our hypothesis. Novice users do model problems differently, and some styles are less efficient for the tool than others. In many cases, the application of source-level transformations corrects those inefficiencies.

1.3 Contribution

The primary contribution of our work is the identification of a new research area. To date, work on optimizing verification has focused on improving the fundamental algorithms. We assert that optimizations which close the gap between novice and expert are also important, and support our assertion with positive experimental results. Furthermore, we identify several source-level transformations which can help to close this gap, and implement one. In the process of evaluating that transformation, we have developed necessary infrastructure for performing optimizations in Murφ 3.1 and identified impediments to implementation of further source-level optimizations. Finally, we provide advice for follow-on research using the Murφ platform.

Chapter 2

Background

In this chapter we provide background on the Murφ verifier, with details on the features which are relevant to our work, and an overview of related work.

2.1 Murφ

We have chosen the Murφ verification system [6, 5] as the basis for our optimizations. The Murφ verifier is a model checker which performs explicit state space reachability.[1] Murφ has been widely used for a variety of applications (e.g., [7, 25, 18, 10, 19, 11]).

The Murφ verifier has it's own input language for describing the system being verified. This Murφ language is a high-level, guarded-command language [4, 3]. A Murφ program consists of two main parts: declarations and rules. The declaration section is Pascal-like and declares constants, types, global variables, and procedures. The rules define the transitions of the system. At any given time, the system state is determined by the values of the global variables. As the system executes, a rule is

[1] For additional information see `http://verify.stanford.edu/dill/murphi.html`.

chosen nondeterministically and executes atomically, updating the global variables to a new state.

Compiling a Murφ model is a two step process. First Murφ transforms the model into a C++ program which verifies the model. Then a C++ compiler is used to turn that program into an executable. Most elements of a Murφ model translate well into C++, with the exception of rule execution. Since Murφ is verifying the model for all possible executions, all rules are attempted for each visited state.

Murφ tracks visited states in a table, which can become very large. Murφ offers two options, bit compaction and hash compaction, to reduce the memory requirements of the state table. These options trade increased computation time for reduced space. Bit compaction packs states rather than word-aligning them, which may have a dramatic impact on the memory requirements of some models. Hash compaction does not store full state information in the state table, but rather stores a hash of the state. At the end of a run Murφ gives the probability of a hash collision on that run. The hash function is different for each run of a model, allowing multiple runs to be used to reduce the overall probability that states have been missed. Bit compaction and hash compaction may be combined.

Murφ provides several features to simplify writing scalable descriptions of large systems. The normal description style uses numerous subrange types, which can be scaled easily. Of particular interest to this thesis are the special `scalarset` and `multiset` types, which provide automatic symmetry reduction [15]. Scalarsets are like subranges, but without order. Multisets are like arrays, except that the array elements are unordered. Appropriate use of these data types greatly reduces the size of the state space. To simplify writing rules for all values of a subrange or scalarset, Murφ provides a `ruleset` construct, which generates a copy of all enclosed

```
Const
  ProcCount: 2;     -- # of processors
  AddressCount: 2;  -- # of addresses
  ValueCount: 2;    -- # of distinct values
  ...
Type
  Pid: Scalarset(ProcCount);
  Address: Scalarset(AddressCount);
  Value: Scalarset(ValueCount);
  ...
  ProcState: Record
               ...
               cache: Array[Address] of
                        Record
                          ...
                          v: Value;
                        End;
             End;
  ...
Var
  procs: Array[Pid] of ProcState;
  ...
Procedure flushCache(p: Pid);
Begin
  ...
End;
...
```

(Figure 2.1, continued on next page)

(continuation of Figure 2.1)

```
Ruleset p: Pid Do
  Alias me: procs[p] Do
    Ruleset a: Address Do
      Ruleset v: Value Do
        Rule "Evict shared data"
          (me.cache[a].state = Shared) ==>
            me.cache[a].state := Invalid;
            Undefine me.cache[a].v;
        Endrule;
        Rule "Change exclusive copy"
          (me.cache[a].state = Exclusive) ==>
            me.cache[a].v := v;
        Endrule;
        ...
        Rule "Processor reset"
          true ==>
            flushCache(p);
        Endrule;
      Endruleset;
    Endruleset;
  Endalias;
Endruleset;
...
```

Figure 2.1: Fragments from a Murφ Model of a Cache Coherence Protocol. The syntax is similar to Pascal, extended to support specifying rules as guarded commands. There are two main sections, for declarations (e.g., `Const`, `Type`, `Var` and `Procedure`) and for rules (e.g., `Ruleset` and `Alias`). The scalarset definitions are like subranges, except that they permit automatic symmetry reduction. In this example, the rulesets instantiate the rules for all possible processors, addresses, and values. The rules shown allow any processor to evict any address that it has cached in the shared state, any processor to change to any value any address that it has cached exclusive, and any processor to flush its cache.

```
Ruleset p: Pid Do
  Alias me: procs[p] Do
    Ruleset a: Address Do
      Ruleset v: Value Do
        Rule "Evict shared data"
          (me.cache[a].state = Shared) ==>
            me.cache[a].state := Invalid;
            Undefine me.cache[a].v;
        Endrule;
      Endruleset;
    Endruleset;
  Endalias;
Endruleset;

Ruleset p: Pid Do
  Alias me: procs[p] Do
    Ruleset a: Address Do
      Ruleset v: Value Do
        Rule "Change exclusive copy"
          (me.cache[a].state = Exclusive) ==>
            me.cache[a].v := v;
        Endrule;
      Endruleset;
    Endruleset;
  Endalias;
Endruleset;
```

Figure 2.2: An example of ungrouping two rules from Figure 2.1.

rules for each possible value of its formal parameter. Similarly, the `choose` construct selects an item from a multiset. Figure 2.1 shows some portions of a Murφ model for a cache coherence protocol.

Murφ allows users to group rules within ruleset, choose, and alias statements, which can be nested arbitrarily. Grouping rules together under ruleset, choose or alias statements is logically equivalent[2] to placing each rule under separate identical

[2]In practice each ruleset, choose, and alias statement incurs a small amount of overhead, so grouping rules can improve performance very slightly.

ruleset, choose or alias statements, as in Figure 2.2.

2.2 Related Work

The general concept of rewriting something to improve downstream performance is widespread, e.g., database query optimization or high-performance numerical code preprocessing, but this concept has not been applied to formal verification.

Optimizing compilers perform source-level transformations, such as loop unrolling, loop distribution, strength reduction, and induction variable removal [1, 20], some of which are similar to the Murφ transformations we propose. Most programming languages are flexible, allowing the same idea to be expressed in many different ways. This flexibility empowers the user to express themselves in whatever way best suits their problem, rather than the way which best suits the compiler. One of the main goals of compiler optimization is to avoid penalizing users who do not express themselves in the way which directly translates to optimum performance. Murφ takes advantage of compiler optimizations by generating C++ code which is then processed by an optimizing C++ compiler. The primary difference with our work is that compiler optimizations seek to optimize code execution speed, while we seek to improve the verification code which is to be compiled.

Within the formal verification community, a great deal of research has gone into reducing memory usage and runtime (for examples, see some recent surveys [2, 8, 16, 9, 17]). These optimizations are written by experts for experts, optimizing the fundamental verification algorithms in ways that rarely can be expressed in the original language. Obviously, this research is complementary to ours; they optimize models written in a particular style, while we transform models written in a variety of styles into the particular styles which subsequently optimize well. The work most

closely related to ours is by Ip [14]. As with our work, he performs high-level analysis of Murφ programs during compilation to accelerate the verification, although again, his optimizations cannot be expressed in the source language, and therefore are not closing the gap between expert and novice.

We have recently become aware of work by Yorav and Grumberg [26], which analyzes the control-flow graph of a Murφ program to reduce the size of the statespace. They attempted two optimizations. One, which they call dead variable reduction, reduces the statespace size by eliminating variables which are no longer used for computation. The optimization is very similar to our variable clearing transformation, described in Section 3.3. The other, called path reduction, shrinks the statespace by shortening computation paths, reducing the number of steps for each computation.

Chapter 3

Source-Level Transformations

In this chapter, we identify a few possible source-code transformations which may improve models written by novice users. These are ruleset rearrangement, scalarset identification, and variable clearing.

3.1 Ruleset Rearrangement

Murφ allows users to group rules within `ruleset`, `choose`, and `alias` statements. These groupings are primarily for convenience; grouping of rules may be the best match for the problem semantics or may make it easier for the user to understand the model.

If a rule is enclosed within a ruleset or choose statement on which it does not depend, the verifier will needlessly execute the rule for each possible value of the enclosing ruleset or choose parameter. The set of reachable states is unaffected, as each firing of that rule for variations of the independent variable will lead to the same state, but every extra rule firing adds to the runtime of the model.

Obviously, rules should be moved outside the scope of irrelevant ruleset and

choose statements. Grouping of rules complicates removal. We will rely on two properties to rewrite the description into an equivalent one that eliminates the needless rule firings:

Notation *Let a* SimpleRule *be any single* `rule` *statement. Let a* Ruleset *be any single* `ruleset`, `choose`, *or* `alias` *expression. Let a* CompoundRule *be any* SimpleRule, *any* Ruleset *enclosing a* CompoundRule, *or any sequence of* CompoundRules. *If* ϕ *is a* CompoundRule, *let* $\langle\phi\rangle$ *denote the* CompoundRule *formed by enclosing* ϕ *in a* Ruleset.

Property 1 *A* CompoundRule ϕ *is equivalent to* $\langle\phi\rangle$ *if* ϕ *does not depend on the enclosing* Ruleset.

Property 2 *Any* Ruleset *enclosing a sequence of* CompoundRules $\langle\phi_1, \phi_2, \ldots, \phi_n\rangle$ *is equivalent to* $\langle\phi_1\rangle, \langle\phi_2\rangle, \ldots, \langle\phi_n\rangle$.

A straightforward implemention method starts by ungrouping all rules, so that each rule is alone within its enclosing ruleset, choose, and alias statements. Then, a check is performed to determine whether each rule is dependent on those enclosing statements. (Our ungrouping is similar to loop distribution [23], and our dependency check is similar to induction variable removal [24].) Independent ruleset and choose statements are removed, resulting in an equivalent model which executes faster. Independent alias removal does not directly impact performance, but it greatly simplifies the dependency analysis of parent ruleset and choose statements, so independent alias statements are also removed. For example, in Figure 2.1 the eviction rule does not depend on the ruleset over v, and the reset rule does not depend on v or a. The transformation would convert the rules as shown in Figure 3.1. Each rule is now enclosed by only the relevant rulesets.

```
Ruleset p: Pid Do
  Alias me: procs[p] Do
    Ruleset a: Address Do
      Rule "Evict shared data"
        (me.cache[a].state = Shared) ==>
          me.cache[a].state := Invalid;
          Undefine me.cache[a].v;
      Endrule;
    Endruleset;
  Endalias;
Endruleset;

Ruleset p: Pid Do
  Alias me: procs[p] Do
    Ruleset a: Address Do
      Ruleset v: Value Do
        Rule "Change exclusive copy"
          (me.cache[a].state = Exclusive) ==>
            me.cache[a].v := v;
        Endrule;
      Endruleset;
    Endruleset;
  Endalias;
Endruleset;

Ruleset p: Pid Do
  Rule "Processor reset"
    true ==>
      flushCache(p);
  Endrule;
Endruleset;
```

Figure 3.1: The result of applying the ruleset rearrangement transformation to the example in Figure 2.1. Note that `"Evict shared data"` and `"Processor reset"` have fewer enclosing rulesets than in Figure 2.2, reducing the number of possible states which must be considered.

The idea of rearranging rulesets is not new, although ours is the first implementation which produces optimal results in all cases. Murφ 3.1 employs an ad hoc heuristic which also attempts to skip some redundant iterations over independent variables. The heuristic shuffles a hierarchy of ruleset and choose statements, leaving rule groupings intact. The rule groupings obscure the dependency structure and defeat most optimizations.

3.2 Scalarset Identification

Using scalarsets instead of subranges in cases where ordering within the range does not matter provides a tremendous reduction in state space size. Subranges, however, cannot always be replaced by scalarsets: any operation that relies on order, arithmetic, or distinguishing special elements in the range breaks symmetry and precludes the use of scalarsets.

Novices might not realize all cases when a scalarset can be used. A trivial possible transformation is to check for each subrange type whether it could be redefined as a scalarset.

A more interesting and powerful transformation is possible if one considers common programming practice. Data types are often reused for various purposes if it seems appropriate. An integer type, for example, might be used for a counter, for arithmetic, and for ID numbers. Returning to the example in Figure 2.1, suppose the user had defined an "integer" type as a subrange, and used this type for addresses, processor IDs, and values, as well as for some counters. In that model, one could not apply the scalarset symmetry reduction to addresses, processor IDs, and values, because the same type is also being used for counters, which have order. Even without the counters, having a single scalarset type for addresses, processor IDs, and

values would not allow as much symmetry reduction as having a separate scalarset for each.

The data type reuse problem suggests a much more powerful solution to identify possible scalarsets. A syntactic check of the Murφ program can determine which variables interact and must have the same type versus which variables have the same type simply for the user's convenience. A graph can be constructed with a node for each variable and edges indicating which variables must be type-compatible. Each connected component of the graph may be assigned a distinct type. Each of these types may then be checked separately for possible conversion to a scalarset.

3.3 Variable Clearing

In most models, not all variables are holding important data at all times. For example, if a cache line is invalid, its contents do not matter, or if a queue is modeled as an array and a tail pointer, the array elements past the tail pointer do not matter.

Although the contents of these variables may not matter to the user or to the accuracy of the model, they do matter to the verification tool. Two states that differ only in the values of don't-matter variables are still considered two distinct states by the verification tool. If the user is not careful to clear any leftover values out of variables whenever the the value no longer matters, the result is a needless explosion in the number of states. For example, in Figure 2.1, if the user omitted the `Undefine` statement, the resulting model would have a much larger set of reachable states, because different values leftover in the `me.cache[a].v` field would generate additional states.

Tracking exactly which variables are no longer needed and making sure to

clear out their values is tedious for the expert user and extremely difficult for the novice, who may not even realize the importance of doing so. Fortunately, live variables analysis, a standard program analysis technique (e.g., [22]), can determine automatically which variables are dead (not needed) at each point in a program. Note that the Murφ execution model, in which rules are chosen nondeterministically, results in a very conservative live variables analysis. Some limited data flow analysis to track rule enabling and disabling might strengthen the analysis considerably. Adapting live variables analysis to Murφ programs could determine where `Undefine` statements are needed. The source-code transformation would insert the `Undefine` statements automatically, greatly improving the efficiency of verification. Recent work by Yorav and Grumberg [26] confirms that this is a promising area of research.

Chapter 4

Implementation

This chapter discusses our implementation work. We begin with an overview of the relevant portions of Murφ, followed by a detailed description of our optimizations. Finally, we will give advice for future optimization projects based on Murφ.

Since it was unlikely that our work would become part of the main Murφ distribution, we wished to avoid major changes to any specific version of the compiler. Murφ's original design called for separate parsing and compilation stages, to allow additional processing stages, such as an optimizer, to be easily inserted between parsing and code generation. Our intent was to write routines which analyzed and then modified the parse tree, and to insert those routines between the parsing and code generation stages, saving us from having to develop our own code for parsing and output. Murφ is a big language, and a full Murφ parser would be complex and time consuming to produce. Unfortunately, the implementation of the current Murφ compiler does not permit insertion of a meaningful optimization stage between the parser and the code generator.

4.1 Murφ 3.1

In this section we discuss the relevant details of the implementation of Murφ 3.1, the current version of the Murφ compiler. There are numerous little details in Murφ 3.1 that make implementing an optimization stage difficult, which are to be expected when modifying a mature program. The little details did not present significant obstacles. Unfortunately, the underlying structure of the Murφ 3.1 compiler was an obstacle, and greatly hindered our efforts.

Although at a high level it appears that Murφ 3.1 still has separate parsing and compilation stages, a more detailed analysis of the source code shows that many aspects of the implementation violate the original object-oriented design. One aspect which proved nearly impossible to work around is that the parse tree is completely ignored after it is created. Code generation is performed using an independent set of data structures, which are generated at parse time along with the parse tree. Those data structures represent a partial compilation of the program. Our source-level transformations cannot be performed on the partially compiled program.

Fortunately, the rule code generation data structure is simple enough that we can regenerate it after performing modifications on our parse tree. This allows us to perform ruleset rearrangement, but none of our other proposed transformations.

4.2 Murφ Optimizer

The ruleset rearrangement transformation is implemented as a modification of Murφ 3.1. We added a small amount of helper code in one class, made necessary adjustments to protections on another class, added the appropriate calls to our code between parsing and code generation, and cleaned up a few problems with

ANSI C++ compliance. Appendix A.3.1 contains a full listing of the changes to Murφ 3.1, in unified diff format.

Our optimizer[1] works in two stages. The first stage traverses Murφ's parse tree, building a new version of that tree. The second stage traverses the new tree, performing any possible optimizations.

The new parse tree is built to overcome deficiencies in the object-orientation of Murφ 3.1. All classes are derived from the same base class, and each class has consistent methods for dependency analysis and optimization. In proper object-oriented fashion, each class knows how to optimize itself. A typical `optimize()` method asks each child of the class to optimize, requests dependency information from those children, and then, based on its own state and the dependencies of its children, will perform transformations on itself. In some cases these transformations require creation of a replacement object based on a different class; such replacement objects are passed to the parent as the return value of `optimize()`.

The ruleset rearrangement transformation requires dependency information from all children of the rule to know whether or not the rule is independent. For the most part, dependency analysis in a Murφ model should be easy. All of a model's state is contained in global variables, and most operations on those global variables are performed in rules, which are easy to analyze. The exception is when rules call functions or procedures. The simplest approach is to assume that all variables passed to a function or procedure are used in that function or procedure, but that may not always be the case. A more thorough approach would be to apply standard interprocedural data-flow analysis [21] to this problem.

Unfortunately, it is very difficult to track variable dependencies in Murφ 3.1.

[1]Full source code for our optimizer may be found in Appendix A, or may be downloaded from `http://www.cs.ubc.ca/labs/isd/Projects/`.

This is because Murφ 3.1 takes advantage of the subsequent C++ compilation step, maintaining as little information as possible about the details of the variable. In the absence of better information, our optimizer currently tracks dependencies by scope.[2] Tracking dependencies by scope is sufficient for simple ruleset rearrangement, but is inadequate for tracing variable use through procedure and function calls.

Ideally our optimizer should not be as large as it is. The extra size comes from recreating many of the structures present in the Murφ compiler. This redundancy is unfortunate, but was necessary given our design goals.

4.3 Suggestions for Future Attempts

Our current Murφ optimizer cannot be extended further without a major overhaul of Murφ 3.1. We believe that to be successful, any future work on source-level Murφ optimization should adopt one of two different approaches.

One approach is to create a source-to-source optimizer. All of our proposed transformations are source-level, so an optimizer could ignore code generation entirely. We believe that because Murφ is a flexible language, many other desirable optimizations could also be performed at the source level. This approach requires writing a Murφ parser, but has the advantage that the program output is a trivial dump of the optimized parse tree.

The other approach is to rewrite Murφ. Such a rewrite should be based on completely separate parse, optimization, and compilation stages. The class structure of our Murφ optimizer could be used as a basis for such a rewrite, but parse and compilation methods would need to be created, which is a nontrivial task. Without

[2]Each `begin/end` block in a Murφ program constitutes a different scope.

borrowing substantial portions of Murφ 3.1 compilation code, this approach also complicates any assertion that the resulting optimized model is equivalent to an unoptimized model produced through Murφ 3.1.

Chapter 5

Experiments

5.1 Methodology

Testing was performed on three sets of Murφ programs. The first set is the examples included in the Murφ distribution. These examples are written by expert Murφ users, so our hypothesis predicts little improvement from our optimization. The second set are eleven implementations of a simple, fictitious directory-based cache coherence protocol, each developed independently by students in a formal verification class. The students had no previous experience with Murφ. They were given a tabular description of the cache coherence protocol and a partial Murφ model that included declarations, but no rules, so they were free to write the rules in whatever manner was most natural for them. This set of programs represents a large number of novice users independently tackling the same verification task. Our hypothesis predicts that some of these should benefit significantly from our optimization. The third experiment is a model of part of the physical layer of the IEEE 1394 [13] High Performance Serial Bus. The model implements the reset and

tree identification portions of the physical layer. The model is significantly larger than the others and was written by the author when he was a Murφ novice. Large, real models written by novices are not widely available, but such models provide the best test of our hypothesis because large real models written by novices are precisely those that we seek to improve.

The Murφ generated C++ code was compiled using egcs version 2.91.66 with "`-O4 -mpentiumpro`" optimization. The Murφ hash table size was set to 96 MB with 30% for the active states. Experiments were run with and without hash compaction. With hash compaction, the default 40-bit hash size was used. The experiments were run on a 400 MHz Pentium II workstation with 128 MB of RAM, running SuSE Linux 6.1.

5.2 Results

The results of the experiments support our hypothesis. The size of the model (lines of code and number of states reached), runtime in seconds with and without optimization, and percent improvement are reported for all models. The runtime reported is the median of five runs, in order to eliminate possible outlier effects.[1]

The results for the set of examples distributed with the Murφ verifier are shown in Tables 5.1 and 5.2. As can be seen, the transformation had little effect on these programs, written by expert Murφ users. This result is as expected by our hypothesis — the goal of our optimization is to improve the source code written by novice users, rather than trying to improve the fundamental verification algorithms. Worth noting, however, is that even this extremely simple transformation was able

[1]Few outliers were observed, with most models showing less than 2% variation, fastest to slowest. Some of the smallest models ($< 1s$ running time) had variations as high as 20%, probably due to measurement error and operating system issues.

Table 5.4: Cache coherence protocol models, with hash compaction. Again, some examples written by novices show significant improvement. These models were run with the same parameters as in Table 5.3.

to give noticeable speedup on one model written by a Murφ expert.

Tables 5.3 and 5.4 show the results for the set of cache coherence protocol models, each developed independently by a different novice user. These models were tested with 2 processors, 3 addresses, and 2 data values. Communication channels were scaled to the minimum value which would allow verification of the model to complete. In this case, our hypothesis predicts that some of these programs should show significant improvement, corresponding to when a particular user chose a writing style that happens not to be well-suited to the internals of the tool. As expected, our simple optimization significantly speeds up two of the eleven programs. The enormous variations in code size, state count, and run times make it clear that different users naturally express themselves differently. A robust formal verification tool should adapt to this diversity, rather than forcing users to write code specifically tailored to the verification tool's idiosyncrasies.

Results for the third test are shown in Tables 5.5 and 5.6. This program[2] is a larger model of a real protocol, part of the IEEE 1394 "Firewire" standard. The program was written by a novice Murφ user for whom the most natural way to model the system did not give the best arrangement of rules and rulesets for efficient Murφ execution. The transformation significantly accelerated this example. It is again clear that novice users do not understand the subtleties of the verification tool, so their models might not be written in the most efficient manner for the tool. A simple source-code transformation helps rectify the problem.

Compile times (Murφ translation plus C++ compilation) for each model are shown in Tables 5.7, 5.8, 5.9, 5.10, 5.11, and 5.12. Times from only one compilation are reported, because the transformation does not significantly affect compile time.

[2]A listing of the model may be found in Appendix B.1.

In absolute terms, the worst compile time increase was 8.5 seconds on an example that required 255 seconds total. In percentage terms, the worst compile time increase was 18% on an example that required 10.2 seconds total.

Chapter 6

Conclusions and Future Work

In this thesis, we assert that closing the gap between novice and expert is an important area for verification research. Novices model problems differently than experts, primarily because they understand less about the underlying tool. We have identified several source-level transformations which promise to improve the verification experience for novice users. After creating the necessary infrastructure to work with Murφ 3.1, we implemented one of those transformations to provide a preliminary test of our hypothesis.

As we have seen, even a single source-level transformation was able to significantly improve several models written by novices. This result supports the assertions that novice users are likely to model systems differently and less efficiently for formal verification, that many of these inefficient modeling choices can be easily detected at the source-code level, and that a verification tool can optimize away these inefficient modeling choices, thereby boosting the productivity of novice users. A tool user should not need to understand the inner details of the tool, nor adapt to those details, in order to use it effectively. This work is a step towards closing the gap

between novice and expert.

Our goal was to illustrate how verification tools should adapt to novice users, rather than to advocate a specific optimization for a specific tool. Nevertheless, the most obvious direction for future work is to try the other proposed transformations and measure their effectiveness. Doing so with Murφ 3.1 would require a great deal of additional effort.

We made a major planning mistake during this project: choosing to modify the existing Murφ 3.1 compiler rather than writing our own parser. The Murφ language is quite large. We chose to avoid the devil we knew, hoping that the underlying code would be easier to manipulate. Then, as the project progressed and the problems mounted, we chose to press on, believing that the next big obstacle would be the last. In retrospect, writing our own source-to-source compiler would have been easier.

Given the structural problems with Murφ 3.1, future source-level optimization work should follow one of two approaches. Creating a source-to-source optimizer is the simpler of the two, and has the advantage that Murφ 3.1 would still be used for code generation, ensuring compatibility. The more comprehensive approach is to rewrite Murφ, maintaining rigid separation between parsing, optimization, and code generation. Although there are greater drawbacks to a full rewrite, including the effort of developing a full compiler and of ensuring compatibility with existing Murφ compilers, the final result would be a more powerful tool.

The more general direction for future work, and the promise of greater impact, is to apply these ideas to other verification tools and languages. Possible questions to investigate include what source-level changes might reduce BDD size, what aspects of Verilog or VHDL might highlight easy-to-implement optimizations,

and how might a future hardware description language or verification language be best designed to support robust ease-of-use. Considerable further research needs to be done.

Appendix A

Murφ Optimizer Source

This appendix contains full source code for our Murφ optimizer. The source is available electronically,[1] but it is included here for archival purposes. The Internet is a powerful dynamic communication medium, but is not well suited for long term data preservation. The last ten years have seen the demise of several file location protocols (e.g., gopher and archie); it is unlikely that HTTP will fare better over time.

The ruleset rearrangement transformation is implemented as a modification of Murφ 3.1. The modifications to the Murφ 3.1 compiler itself are minimal, and listed in Section A.3.1 in unified diff format. The bulk of the optimizer mirrors the structure of the Murφ parse tree, with methods for manipulating the tree and for updating the necessary Murφ 3.1 data structures for code generation. C++ header files are presented first, followed by the associated C++ code files and finally other support files.

[1] At publication time, from `http://www.cs.ubc.ca/labs/isd/Projects/`.

A.1 C++ Header Files

A.1.1 mu_opt.h

```
// mu_opt.h    -*- c++ -*-

#ifndef MU_OPT_H
#define MU_OPT_H

//#include "mu_opt_base.h"
//#include "mu_opt_ste.h"
//#include "mu_opt_stmt.h"
//#include "mu_opt_decl.h"
//#include "mu_opt_rule.h"
#include "mu_opt_root.h"

#endif /* MU_OPT_H */
```

A.1.2 mu_opt_base.h

```
// mu_opt_base.h    -*- c++ -*-

#ifndef MU_OPT_BASE_H
#define MU_OPT_BASE_H

#include <mu.h>
#include <iostream.h>
#include <list>
#include <set>

//#define MUOPT_DEBUG

Appendix B

Firewire Model Source

B.1 Novice Firewire Model

This partial model of IEEE 1394 [13] is the one tested in Chapter 5. It was written Fall 1998, by the author, at the beginning of his graduate studies. At that time the author was a Murφ novice. The model is a part of the cable physical layer [12], specifically the bus reset and tree identification state machines.

-- Revision history:
--   11/24/98   Worked out startup problems.  Able to reach all states up
--              to S0 (all I've implemented so far).  Statespace blows up
--              doing full evaluation of that statespace though.
--   11/22/98   Have the standard.  Implementing PHY from their code.
--   11/10/98   Started using CVS (I'm sleeping better already).
--              Implementing cables between nodes as a resolution function
--                of the outputs of those two nodes.
--   11/03/98   Initial version.  Linear arrangement of N nodes.

const
  N: 2;              -- number of nodes
  HIGHPORT: 1;       -- highest numbered port possible per node
--HIGHFIFO_DEPTH: 0; -- highest numbered entry in a FIFO

B.2 Later Firewire Model

Our work on modeling firewire ended in March 1999. The final model, covering all of the cable physical layer initialization, leaves little room for source level transformation, reflecting the increased Murφ experience of the author and feedback from other experienced Murφ users. It is included here for archival purposes.
