# Markov Decision Processes

#### Definition (Markov Decision Process)

A Markov Decision Process (MDP) is a 5-tuple  $\langle S, A, P, R, s_0 \rangle$ , where each element is defined as follows:

- S: a set of states.
- A: a set of actions.
- $P(S_{t+1}|S_t, A_t)$ : the dynamics.
- $R(S_t, A_t, S_{t+1})$ : the reward. The agent gets a reward at each time step (rather than just a final reward).
  - R(s, a, s') is the reward received when the agent is in state s, does action a and ends up in state s'.
- s<sub>0</sub>: the initial state.

## **Rewards and Values**

Suppose the agent receives the sequence of rewards  $r_1, r_2, r_3, r_4, \ldots$  What value should be assigned?

• total reward:

$$V = \sum_{i=1}^{\infty} r_i$$

• average reward:

$$V = \lim_{n \to \infty} \frac{r_1 + \dots + r_n}{n}$$

• discounted reward:

$$V = \sum_{i=1}^{\infty} \gamma^{i-1} r_i$$

•  $\gamma$  is the discount factor,  $0\leq\gamma\leq 1$ 

**Decision Theory: Value Iteration** 

### Policies

• A stationary policy is a function:

 $\pi:S\to A$ 

Given a state  $s,\,\pi(s)$  specifies what action the agent who is following  $\pi$  will do.

- An optimal policy is one with maximum expected value
  - we'll focus on the case where value is defined as discounted reward.
- For an MDP with stationary dynamics and rewards with infinite or indefinite horizon, there is always an optimal stationary policy in this case.
- Note: this means that although the environment is random, there's no benefit for the *agent* to randomize.

▶ < 별 ▶ < 별 ▶</p>

## Value of a Policy

- $Q^{\pi}(s, a)$ , where a is an action and s is a state, is the expected value of doing a in state s, then following policy  $\pi$ .
- V<sup>π</sup>(s), where s is a state, is the expected value of following policy π in state s.
- $Q^{\pi}$  and  $V^{\pi}$  can be defined mutually recursively:

$$V^{\pi}(s) = Q^{\pi}(s, \pi(s))$$
  

$$Q^{\pi}(s, a) = \sum_{s'} P(s'|a, s) \left( r(s, a, s') + \gamma V^{\pi}(s') \right)$$

伺 と く き と く き と

### Value of the Optimal Policy

- $Q^*(s, a)$ , where a is an action and s is a state, is the expected value of doing a in state s, then following the optimal policy.
- $V^*(s)$ , where s is a state, is the expected value of following the optimal policy in state s.
- $Q^*$  and  $V^*$  can be defined mutually recursively:

$$Q^{*}(s, a) = \sum_{s'} P(s'|a, s) \left( r(s, a, s') + \gamma V^{*}(s') \right)$$
  

$$V^{*}(s) = \max_{a} Q^{*}(s, a)$$
  

$$\pi^{*}(s) = \arg\max_{a} Q^{*}(s, a)$$

## Value Iteration

- Idea: Given an estimate of the k-step lookahead value function, determine the k + 1 step lookahead value function.
- Set V<sub>0</sub> arbitrarily.
  - e.g., zeros
- Compute  $Q_{i+1}$  and  $V_{i+1}$  from  $V_i$ :

$$Q_{i+1}(s,a) = \sum_{s'} P(s'|a,s) \left( r(s,a,s') + \gamma V_i(s') \right)$$
  
$$V_{i+1}(s) = \max_{a} Q_{i+1}(s,a)$$

• If we intersect these equations at  $Q_{i+1}$ , we get an update equation for V:

$$V_{i+1}(s) = \max_{a} \sum_{s'} P(s'|a, s) \left( r(s, a, s') + \gamma V_i(s') \right)$$

## Pseudocode for Value Iteration

```
procedure value_iteration(P, r, \theta)
```

inputs:

```
P is state transition function specifying P(s'|a, s)
```

```
r is a reward function R(s, a, s')
```

 $\theta$  a threshold  $\theta > 0$ 

#### returns:

 $\pi[s]$  approximately optimal policy

V[s] value function

#### data structures:

 $V_k[s]$  a sequence of value functions

begin

```
for k = 1 : \infty
for each state s
V_k[s] = \max_a \sum_{s'} P(s'|a, s)(R(s, a, s') + \gamma V_{k-1}[s'])
if \forall s | V_k(s) - V_{k-1}(s) | < \theta
for each state s
\pi(s) = \arg \max_a \sum_{s'} P(s'|a, s)(R(s, a, s') + \gamma V_{k-1}[s'])
return \pi, V_k
```

end
