Textbook §2.5

Lecture Overview

Depth-first Search

- Depth-first search treats the frontier as a stack
  - It always selects one of the last elements added to the frontier.

- Complete when the graph has no cycles and is finite
- Time complexity is $O(b^m)$
- Space complexity is $O(bm)$

Breadth-first Search

- Breadth-first search treats the frontier as a queue
  - it always selects one of the earliest elements added to the frontier.

- Complete when the graph has no cycles and is finite
- Time complexity is $O(b^m)$
- Space complexity is $O(b^m)$

Search with Costs

- Sometimes there are costs associated with arcs.
  - The cost of a path is the sum of the costs of its arcs.

$$cost(\langle n_0, \ldots, n_k \rangle) = \sum_{i=1}^{k} |\langle n_{i-1}, n_i \rangle|$$

- An optimal sarch algorithm always finds the solution that minimizes cost

Lowest-Cost-First Search

- At each stage, lowest-cost-first search selects a path on the frontier with lowest cost.
  - The frontier is a priority queue ordered by path cost.

- Complete when the graph has strictly positive arc costs
- Time complexity is $O(b^m)$
- Space complexity is $O(b^m)$
- Optimal when the graph has non-negative arc costs

Past knowledge and search

- Some people believe that they are good at solving hard problems without search
  - However, consider e.g., public key encryption codes (or combination locks): the search problem is clear, but people can't solve it
  - When people do perform well on hard problems, it is usually because they have useful knowledge about the structure of the problem domain
- Computers can also improve their performance when given this sort of knowledge
  - in search, they can estimate the distance from a given node to the goal through a search heuristic
  - in this way, they can take the goal into account when selecting path

Heuristic Search

- $h(n)$ is an estimate of the cost of the shortest path from node n to a goal node.
  - h can be extended to paths: $h(\langle n_0, \ldots, n_k \rangle) = h(n_k)$
- $h(n)$ uses only readily obtainable information (that is easy to compute) about a node.
- Admissible heuristic: $h(n)$ is an underestimate if there is no path from n to a goal that has path length less than $h(n)$.

Example Heuristic Functions

- If the nodes are points on a Euclidean plane and the cost is the distance, we can use the straight-line distance from n to the closest goal as the value of $h(n)$.
  - this makes sense if there are obstacles, or for other reasons not all adjacent nodes share an arc
- Likewise, if nodes are cells in a grid and the cost is the number of steps, we can use "Manhattan distance"
  - this is also known as the L_1 distance; Euclidean distance is L_2 distance
- In the 8-puzzle, we can use the number of moves between each tile's current position and its position in the solution

How to Construct a Heuristic

- Overall, a cost-minimizing search problem is a constrained optimization problem
  - e.g., find a path from A to B which minimizes distance traveled, subject to the constraint that the robot can't move through walls
- A relaxed version of the problem is a version of the problem where one or more constraints have been dropped
  - e.g., find a path from A to B which minimizes distance traveled, *allowing* the agent to move through walls
  - A relaxed version of a minimization problem will always return a value which is weakly smaller than the original value: thus, it's an admissible heuristic

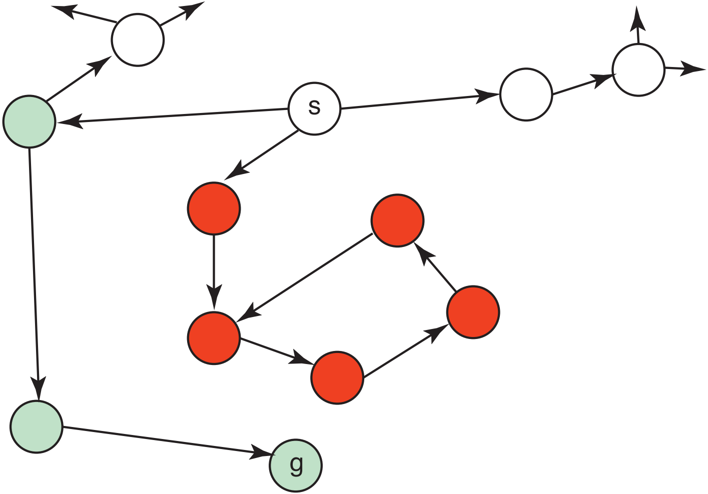
How to Construct a Heuristic

- It's usually possible to identify constraints which, when dropped, make the problem extremely easy to solve
  - this is important because heuristics are not useful if they're as hard to solve as the original problem!
- Another trick for constructing heuristics: if $h_1(n)$ is an admissible heuristic, and $h_2(n)$ is also an admissible heuristic, then $\min(h_1(n), h_2(n))$ is also admissible.

Best-First Search

- Idea: select the path whose end is closest to a goal according to the heuristic function.
- Best-First search selects a path on the frontier with minimal h-value.
- It treats the frontier as a priority queue ordered by h.
- This is a greedy approach: it always takes the path which appears locally best

Illustrative Graph — Best-First Search



Complexity of Best-First Search

- Complete: no: a heuristic of zero for an arc that returns to the same state can be followed forever.
- Time complexity is $O(b^m)$
- Space complexity is $O(b^m)$
- Optimal: no (why not?)
