×.

ABSTRACT

Constraint satisfaction problems can be solved by network consistency algorithms that eliminate local inconsistencies before constructing global solutions. We describe a new algorithm that is useful when the variable domains can be structured hierarchically into recursive subsets with common properties and common relationships to subsets of the domain values for related variables. The algorithm, HAC, uses a technique known as hierarchical arc consistency. Its performance is analyzed theoretically and the conditions under which it is an improvement are outlined. The use of HAC in a program for understanding sketch maps, Mapsee3, is briefly discussed and experimental results consistent with the theory are reported.

Key Words: constraint satisfaction problems, network consistency algorithms, arc consistency, map understanding, computational vision

1. Introduction

In this paper we show how to exploit aspects of the intrinsic structure of variable domains when using a network consistency algorithm to solve a constraint satisfaction problem. A prerequisite brief review of the basic concepts is presented first. For a fuller explanation the reader should consult the original material (Waltz, 1972; Montanari, 1974; Mackworth, 1977a; Freuder, 1978; Haralick and Elliott, 1980; Mackworth and Freuder, 1984).

1.1 Constraint Satisfaction and Network Consistency

A constraint satisfaction problem (CSP) is defined as follows: Given a set of n variables each with an associated domain and a set of constraining relations each involving a subset of the variables, find all possible n-tuples such that each n-tuple is an instantiation of the n variables satisfying the relations. In this paper we shall only consider CSP's in which the relations are unary and binary. This restriction is not necessary for consistency techniques to be applied (Mackworth, 1977b; Freuder, 1978).

Since graph colouring is an NP-complete CSP it is most unlikely that a polynomial time algorithm exists for solving general CSP's. Accordingly, the class of network consistency algorithms was invented. These algorithms do not necessarily solve a CSP completely but they

-3-

eliminate, once and for all, local inconsistencies that cannot participate in any global solutions. These inconsistencies would otherwise have been repeatedly discovered by any backtracking solution. One role for network consistency algorithms is as a preprocessor for subsequent backtrack search, or they can be interspersed with case analysis or simple domain splitting to recover the complete set of solutions to the CSP. A k-consistency algorithm removes all inconsistencies involving all subsets of size k of the n variables. For example, the node, arc and path consistency algorithms detect and eliminate inconsistencies involving k = 1, 2 and 3 variables, respectively. Freuder (1978) generalized those algorithms for k = 1,...,n thereby producing the complete set of solutions to the CSP.

1.2 Node and Arc Consistency

The algorithms below are reprinted from a previous paper (Mackworth, 1977a) which should be consulted for a full explanation. The domain of variable x_i is D_i , P_i is the unary predicate on x_i and P_{ij} is the binary constraint predicate on the variables x_i and x_j corresponding to an edge between vertices v_i and v_j in the constraint graph G. The edge between i and j is replaced by the directed arc from i to j and the arc from j to i as they are treated separately by the algorithms. Let the number of variables be n, the number of binary constraints be e (the number of edges in the constraint graph) and the edge degree of v_i be d_i . The time unit used for our complexity measures is the application of a unary or binary predicate. To simplify the description of the complexity results, in this section we assume that each D_i is the same initial size, a.

The node consistency algorithm NC-1 simply ensures that all values in D_i satisfy P_i by removing those that do not.

procedure NC (i): $D_i \leftarrow D_i \cap \{x \mid P_i (x)\}$

begin for $i \leftarrow 1$ until n do NC(i) end

NC-1: the node consistency algorithm

An arc consistency algorithm is a symbolic relaxation algorithm that establishes the strong arc consistency condition on each arc of G. The arc (i, j) from v_i to v_j is strongly arc consistent iff:

$1 - v_i$ is node consistent

and

2 - For each value in D_i there is at least one value in D_j that is compatible with it (such that P_{ij} is satisfied).

The algorithm AC-3 (Mackworth, 1977a) is an efficient arc consistency algorithm:

```
procedure REVISE ((i, j)):

begin

DELETE \leftarrow false

for each x \in D_i do

if there is no y \in D_j such that P_{ij}(x, y) then

begin

delete x from D_i

DELETE \leftarrow true

end;

return DELETE

end
```

```
1 begin
2
     for i \leftarrow 1 until n do NC(i)
     Q \leftarrow \{(i,j) \mid (i,j) \in arcs(G), i \neq j\}
3
     while Q not empty do
4
5
        begin
6
            select and delete any arc (k, m) from Q
           if REVISE ((k, m)) then Q \leftarrow Q \cup \{(i, k) \mid (i, k) \in arcs(G),
7
                                                                    i \neq k, i \neq m
8
        end
```

```
9 end
```

```
AC-3: an arc consistency algorithm
```

REVISE ((i, y)) makes arc (i, j) strongly arc consistent. AC-3 applies REVISE to each arc of G in turn. It only reconsiders arc (i, j)if it has potentially become inconsistent again because of a deletion from D_j .

Mackworth and Freuder (1984) showed that the time complexity of AC-3 is at best $\Omega(a^2e)$ and at worst $O(a^3e)$. This somewhat surprising worst case behavior for a relaxation algorithm, linear in the number of constraints, confirms the empirical results of using AC-3 in several experimental systems (Waltz, 1972; Mackworth, 1977b; Havens and Mackworth, 1983). The time complexity does depend heavily on the domain size, *a*. As more realistic problems are tackled the domain size increases substantially. Accordingly we were motivated to look for ways of coping with larger domain sizes.

2. Intensional Domains and Predicates

The arc consistency algorithm described above, AC-3, assumes that the domains are supplied extensionally as unstructured sets, listing the finite number of members. Consistency techniques can, however, be applied to CSP's in which the domains do not satisfy that assumption. For example, the domains could be supplied intensionally as descriptions. For any infinite domain this is clearly a necessity. A good example of this is space planning (Mackworth, 1977a).

In a two-dimensional facility or VLSI layout problem the domains (possible placements of the objects) might be given intensionally as subsets of R^2 by describing their boundaries. The constraints, similarly, would be described as intensional predicates. The only necessary adequacy requirement on domain and constraint representations is that they allow one to carry out the domain restriction operation of REVISE. The version of REVISE used by AC-3 assumes an extensional, unstructured set representation of D_i . A more abstract definition of REVISE that does not make that assumption is as follows:

1 procedure REVISE-A(
$$(i, j)$$
):
2 begin
3 $\Delta \leftarrow \{x \mid (x \epsilon \Delta_i) \land [(\exists y)(y \epsilon \Delta_j) \land P_{ij}(x, y)]\};$
4 DELETE $\leftarrow (\Delta \subset \Delta_i);$
5 if DELETE then $\Delta_i \leftarrow \Delta;$
6 return DELETE
7 end

We are now using Δ_i to represent the dynamic value of the currently permissible domain of variable v_i , which monotonically decreases in size. The set of domains, $\{\Delta_i\}$, will have to be initialized by the following statement to be inserted into AC-3 between steps 1 and 2:

1.5 for
$$i \leftarrow 1$$
 until $n \text{ do } \Delta_i \leftarrow D_i$

and similarly NC(i) becomes:

procedure NC(i): $\Delta_i \leftarrow \Delta_i \cap \{x \mid P_i(x)\}$

Line 3 of REVISE-A is the domain restriction operation. If the proper subset test of line 4 sets DELETE to **true** then the restricted domain Δ replaces the old value of Δ_i and REVISE-A returns **true** to indicate that a domain restriction has occurred. If AC-3 uses REVISE-A instead of REVISE then it is suitable for this more general class of CSP's, provided, of course, that the domain and predicate representations used by NC and REVISE-A allow the domain restrictions. Incidentally, in the language of relational database theory (Maier, 1983) the domain restriction of REVISE-A is a semi-join. However, in general, relational data base theory makes *the extensional assumption*, both for the domains and the relations.

3. Hierarchical Domains

Another technique for handling large domains is to exploit their internal structure. Indeed for many real world problems the domain elements often cluster into sets with common properties and relations. Those sets, in turn, group to form higher level sets. This clustering or categorization into "natural kinds" can be represented as a specialization/generalization (is-a) hierarchy (Havens and Mackworth, 1983). The main theme of this paper is the exploitation of the structure provided when the domains can be naturally represented as specialization hierarchies. Each domain can be interpreted as a domain graph with each vertex corresponding to a set of elements and each arc the subset relation between sets. Domain graphs are, of course, quite distinct from the constraint graphs introduced earlier.

In general a domain graph is not a strict tree since a set may be a direct subset of more than one superset; the general characterization of the resultant "tangled" hierarchy is as a directed acyclic graph

-10-

representing the lattice induced by the partial ordering of the subset relation. For the purposes of this paper we shall assume that the domain hierarchies are singly-rooted strict trees. Each subset has only one direct superset and the subsets of a set are mutually exclusive and exhaustive. Without further loss of generality, we shall assume that the trees are binary: the root represents the entire domain, each nonsingleton set has two subsets, and the leaves are the singleton sets, one for each domain element.

The aim is to make REVISE, the inner loop of AC-3, considerably more efficient by reducing the number of predicate evaluations it must perform. The currently active elements of a domain can be represented by a set of tree vertices that dominate those members. REVISE can then retain, delete, or further examine entire subsets of the domain with one or two predicate evaluations.

For the sake of relative simplicity in the notation, we shall assume that each domain D_i can be structured as a balanced binary tree of depth m thus all the domains have the same number of elements: $a = 2^m$. We shall use D_i to represent the original domain for variable x_i and Δ_i to represent the active subset of D_i for x_i at any point in the symbolic relaxation process. Δ_i may be implemented as a set of the active subdomains of D_i . The subdomains of D_i are $\{D_i^{ks}\}$ which can be arranged as a tree as shown in Figure 1, where an arc indicates that the subdomain at the bottom of the arc is a direct subset of the

-11-

subdomain at the top. The notation for D_i^{ks} indicates that it is on the k th level of the domain tree for D_i and it is the s th subdomain at that level.

-13-

The following conditions obtain on the subdomains:

For k

8

$$= 1, \dots, m$$

$$= 1, \dots, 2^{m-k}$$

$$D_i^{ks} = D_i^{(k-1)2s} \cup D_i^{(k-1)2s+1}$$

$$D_i^{(k-1)2s} \cap D_i^{(k-1)(2s+1)} = \emptyset$$

$$|D_i^{ks}| = 2^k$$

$$|D_i^{oo}| = 1$$

In the algorithm we shall develop, Δ_i , the set of still active elements of the original D_i , is the union of a number of mutually exclusive sets,

 D_i^{ks} . At all times, $\Delta_i \subseteq D_i$.

Suppose
$$\Delta_i = \bigcup_q \Delta_i^q$$

and
$$\Delta_j = \bigcup_r \Delta_j^r$$

We call each Δ_i^{q} an abstract label of Δ_i . Each abstract label is identical to a D_i^{ks} for some k and s. In the algorithm, Δ_i is represented by the set $\{\Delta_i^{q}\}$.

We must now efficiently implement the domain restriction step of REVISE-A:

3 $\Delta \leftarrow \{x \mid (x \in \Delta_i) \land [(\exists y)(y \in \Delta_j) \land Pij(x,y)]$

Informally, what we wish to do is test each abstract label Δ_i^{q} of Δ_i , using a generalized version of REVISE. If there is a Δ_j^{r} such that every domain element in Δ_i^{q} is compatible with some in Δ_j^{r} then Δ_i^{q} survives unchanged in Δ_i . If not, then check to see if there is a Δ_j^{r} such that some element in Δ_i^{q} is compatible with some element in Δ_j^{r} . If not then Δ_i^{q} is simply removed from Δ_i . If there is such a Δ_j^{r} then Δ_i^{q} is replaced in Δ_i by its two child subdomains. When all Δ_i^{q} subsets of Δ_i have been processed this way (including the new ones generated in the course of processing) then the arc (i, j) is arc consistent.

We generalize the definition of arc consistency as follows. An abstract label pair $(\Delta_i^{q}, \Delta_j^{\tau})$ is strongly hierarchically arc consistent iff the set of leaf labels below Δ_i^{q} is strongly arc consistent with the set of leaf labels below Δ_j^{τ} . The arc (i, j) is strongly hierarchically arc consistent iff each abstract label of Δ_i is strongly hierarchically arc consistent with some abstract label of Δ_j .

4. Hierarchical Predicates

In order to implement a generalized REVISE we need two new sets of predicates derived from $P_{ij}(x,y)$. These are predicates on the abstract labels D_i^{ks} needed to carry out the operations described above. We define $A_{ij}^{kl}(D_i^{ks}, D_j^{lt})$ to be true iff for all elements belonging to D_i^{ks} there is an element of D_j^{lt} compatible with it. Analogously we define $S_{ij}^{kl}(D_i^{ks}, D_j^{lt})$ to be true iff for some element belonging to D_i^{ks} there is an element of D_j^{lt} compatible with it.

$$A_{ij}^{kl}(D_i^{ks}, D_j^{lt}) \text{ iff } (\forall x \in D_i^{ks}) (\exists y \in D_j^{lt}) P_{ij}(x, y)$$

We can compute A_{ij}^{kl} inductively on k and l as follows:

Suppose

$$D_i = \{a_s | s = 1, 2, \dots, 2^m\}$$

and

$$D_i = \{b_t | t = 1, 2, \dots, 2^m\}$$

then let
$$D_i^{0s} = \{a_s\}$$
 and $D_j^{0t} = \{b_t\}$

$$[1] \quad A_{ij}^{00}(D_i^{0s}, D_j^{0t}) = P_{ij}(a_s, b_t)$$

$$[2] \quad A_{ij}^{0l}(D_i^{0e}, D_j^{lt}) = A_{ij}^{0,l-1}(D_i^{0e}, D_j^{(l-1)(2t-1)}) \vee A_{ij}^{0,l-1}(D_i^{0e}, D_j^{(l-1)2t})$$

for
$$l = 1, 2, ..., m$$

$$[3] \quad A_{ij}^{kl}(D_i^{ks}, D_j^{lt}) = A_{ij}^{(k-1)l}(D_i^{(k-1)(2s-1)}, D_j^{lt}) \wedge A_{ij}^{(k-1)l}(D_i^{(k-1)2s}, D_j^{lt})$$

for
$$k = 1, 2, \dots, m$$

and
$$l = 1, 2, ..., m$$

Suppose, as a simple example, that:

$$D_1 = \{a_1, a_2, a_3, a_4\}$$
 $D_2 = \{b_1, b_2, b_3, b_4\}$

then $D_1^{00} = \{a_1\}$ $D_1^{01} = \{a_2\}$ $D_1^{02} = \{a_3\}$ $D_1^{03} = \{a_4\}$

$$D_1^{10} = \{a_1, a_2\} \quad D_1^{11} = \{a_3, a_4\}$$

$$D_1^{20} = \{a_1, a_2, a_3, a_4\}$$

and $D_2^{00} = \{b_1\}$ $D_2^{01} = \{b_2\}$ $D_2^{02} = \{b_3\}$ $D_2^{03} = \{b_4\}$

$$D_2^{10} = \{b_1, b_2\} \quad D_2^{11} = \{b_3, b_4\}$$

$$D_2^{20} = \{b_1, b_2, b_3, b_4\}$$

We are given the predicate $P_{12}(a_s, b_t)$ as a relation matrix.

$$P_{12}: \begin{array}{c} a_1 \\ a_2 \\ a_3 \\ a_4 \end{array} \begin{pmatrix} 1 & 1 & 1 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 \\ \end{array}$$

We have $A_{12}^{00} = P_{12}$.

Then we compute A_{12}^{01} by pairwise ORing together pairs of columns of A_{12}^{00} using equation [2].

 $A_{12}^{\ 01}: \begin{pmatrix} 1 & 1 \\ 1 & 0 \\ 0 & 1 \\ 0 & 1 \end{pmatrix}$

and, then we compute A_{12}^{02} from A_{12}^{01}

 $A_{12}^{02}: \begin{bmatrix} 1\\1\\1\\1 \end{bmatrix}$

Using equation [3], A_{12}^{10} results from pairwise ANDing the rows of A_{12}^{00} .

 $A_{12}^{10}: \begin{pmatrix} 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix}$

Similarly, A_{12}^{11} results from pairwise ANDing the rows of A_{12}^{01} .

 $A_{12}^{11}: \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$

Parenthetically, for those readers somewhat bemused by the thicket of formal notation, let us remind you what this means. For example, the entry in the first row of the second column of A_{12}^{11} is a 0 which indicates it is not true that for all elements of $D_1^{10} = \{a_0, a_1\}$ there is an element of D_2^{11} such that P_{ij} is satisfied.

 A_{12}^{12} is computed by ANDing together the rows of A_{12}^{02} .

 $A_{12}^{12} = \begin{pmatrix} 1 \\ 1 \end{pmatrix}$

Finally, we obtain A_{12}^{20} , A_{12}^{21} and A_{12}^{22} by ANDing the rows of A_{12}^{10} , A_{12}^{11} and A_{12}^{12} , respectively.

 $A_{12}^{\ 20}:(0\ 0\ 0\ 0)$

 A_{12}^{21} : (0 0)

 A_{12}^{22} : (1)

We also define a set of predicates S_{ij}^{kl} where $S_{ij}^{kl} (D_i^{ks}, D_i^{lt})$ is true iff for some member of abstract label D_i^{ks} there is a member of abstract label D_j^{lt} compatible with it.

$$S_{ij}^{kl}(D_i^{ks}, D_j^{lt})$$
 iff $(\exists x \in D_i^{ks})(\exists y \in D_j^{lt})P_{ij}(x, y)$

We can also compute S_{ij}^{kl} inductively on k and l from the base predicate P_{ij} as follows:

$$S_{ij}^{00}(D_i^{0s}, D_j^{0t}) = P_{ij}(a_s, b_t)$$

where

[4]
$$D_i^{0s} = \{a_s\}$$
 and $D_j^{0t} = \{b_t\}$

$$[5] \quad S_{ij}^{0l}(D_i^{0s}, D_j^{lt}) = S_{ij}^{0(l-1)}(D_i^{0s}, D_j^{(l-1)(2t-1)}) \lor S_{ij}^{0(l-1)}(D_i^{0s}, D_j^{(l-1)2t})$$

for $l = 1, \dots, m$

and

$$[6] \quad S_{ij}^{kl}(D_i^{ks}, D_j^{lt}) = S_{ij}^{(k-1)l}(D_i^{(k-1)(2s-1)}, D_j^{lt}) \lor S_{ij}^{k-1l}(D_i^{(k-1)2s}, D_j^{lt})$$

In other words the hierarchy of S_{ij} predicates is computed by collapsing P_{ij} : ORing together pairs of rows or pairs of columns.

For our example:

•

5	00 12	:	$ \begin{bmatrix} 1 \\ 1 \\ 0 \\ 0 \end{bmatrix} $	1 1 0 0	1 0 1 1	0 0 0 0
S	01 12	:	$ \begin{bmatrix} 1 \\ 1 \\ 0 \\ 0 \end{bmatrix} $	1 0 1 1		
S	02 12	:	$ \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} $)		
S	10 12	:	(¹ ₀	1 0	1 1	0 0)
S	11 12	:	(<mark>1</mark> 0	1 1	ļ	
S	12 12	:	(¹ ₁)		
·S	20 12	:	(1	1 1	0)
S	21 12	:	(1	1)		

 $S_{12}^{\ 22}:(1)$

We distinguish the arc (i, j) from the arc (j, i). Observe that:

 $P_{ji} = (P_{ij})^T$

and so
$$A_{ji}^{00} = (A_{ij}^{00})^T$$

and
$$S_{ij}^{00} = (S_{ij})^T$$

However A_{ji}^{lk} is, in general, not equal to $(A_{ij}^{kl})^T$. It is always the case, however, that $S_{ji}^{lk} = (S_{ij}^{kl})^T$. In our example:

$$A_{21}^{00} = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

$$A_{21}^{\ 01} = \begin{pmatrix} 1 & 0 \\ 1 & 0 \\ 1 & 1 \\ 0 & 0 \end{pmatrix}$$

$$A_{21}^{11} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$$

whereas

$$(A_{12}^{11})^T = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$$

5. Hierarchical Arc Consistency

We are now in a position to define a generalized hierarchical arc consistency algorithm to be known as HAC. HAC uses the general relaxation structure of AC-3 but uses REVISE-HAC as an instantiation of REVISE-A.

In particular step 3 of REVISE-A is:

3
$$\Delta \leftarrow \{x \mid (x \in \Delta_i) \land [(\exists y)(y \in \Delta_j) \land P_{ij}(x, y)\}$$

where
$$\Delta_i = \bigcup_q \Delta_i^q$$
 and $\Delta_j = \bigcup_r \Delta_j^r$

as described earlier.

Step 3 can be implemented using the hierarchical predicates A and S, defined above. Δ_i is represented by a list of its abstract labels Δ_i^{q} and similarly for Δ_j .

procedure REVISE-HAC ((i, j)): 1 2 begin 3 DELETE - false 4 $Q_1 \leftarrow \Delta_i$ $\Delta_i \leftarrow \emptyset$ 5 while Q_1 not empty do 6 7 begin select and delete an element D_i^{ks} from Q_1 8 $Q_2 \leftarrow \Delta_i$ 9 FOUND - false 10 while Q_2 not empty and not FOUND do 11 12 begin select and delete an element D_j^{lt} from Q_2 13 if $A_{ij}(D_i^{ks}, D_j^{lt})$ then 14 begin 15 $\Delta_i \leftarrow \Delta_i \cup \{D_i^{k_0}\}$ 16 17 FOUND - true 18 end 19 end 20 if not FOUND then 21 begin 22 DELETE - true 23 if k > 0 then 24 begin 25 $Q_2 \leftarrow \Delta_i$ while Q_2 not empty and not FOUND do 26 27 begin select and delete an element D_j^{lt} from Q_2 28 if $S_{ij}^{kl}(D_i^{ks}, D_j^{lt})$ then 29 begin 30 $Q_1 \leftarrow Q_1 \cup \{D_i^{(k-1)(2s-1)}, D_i^{(k-1)2s}\}$ 31 FOUND ← true 32 33 end end 34 35 end 36 end 37 end 38 return DELETE 39 end

REVISE-HAC: domain restriction for hierarchical arc consistency

-25-

```
procedure NC (i):
       \Delta_i \leftarrow D_i \cap \{x \mid P_i(x)\}
1
       begin
       for i \leftarrow 1 until n do NC (i)
2
       Q \leftarrow \{(i,j)|(i,j) \in \arccos(G), i \neq j\}
3
       while Q not empty do
4
5
           begin
           select and delete any arc (k, m) from Q
6
           if REVISE-HAC ((k, m))
7
              then Q \leftarrow Q \cup \{(i,k) | (i,k) \in \arccos(G), i \neq k, i \neq m \}
8
9
           end
10
       end
```

HAC: the hierarchical arc consistency algorithm

REVISE-HAC implements the generalized arc consistency algorithm introduced in Section 3. In particular after the application of REVISE-HAC to arc (i, j) that arc will be strongly hierarchically arc consistent in the sense defined earlier. The loop defined in lines 6-37 tests each abstract label in Δ_i to see if it is hierarchically consistent. It does that by testing the label D_i from Δ_i against the abstract labels in Δ_j . The loop in lines 11-19 looks for a label D_j^{lt} in Δ_j such that A_{ij} . If every label below D_i^{ks} is compatible with some label below D_j^{lt} then A_{ij} is true. In that case, D_i^{ks} survives unchanged in Δ_i . If not and D_i^{ks} is not a leaf (k > 0) then lines 20-36 look for a label in Δ_j such that some label below D_i^{ks} is compatible with some label below D_j^{lt} in which case S_{ij} is true. If such a label is found then the label D_i^{ks} is replaced by its two successors in Q_1 . They must be tested similarly on

-26-

 A_{ij} and S_{ij} before this invocation of REVISE-HAC returns. It is clear that Δ_i starts as the empty set and adds members only at line 16 when $A_{ij}(D_i^{kl}, D_j^{ll})$ is true and so when REVISE-HAC returns all members of Δ_i are strongly arc consistent with some abstract label in Δ_j , and so the algorithm is correct. Since the domain trees are non-cyclic and the queues Q_1 and Q_2 decrease monotonically in size (except at line 28 where a finite total number of elements can be added to Q_2) the procedure must terminate. The symbolic relaxation algorithm that has the form of the modified AC-3 but uses REVISE-HAC is known as HAC.

6. Complexity Results

The algorithm AC-3 requires time linear in the number of constraints. As we remarked earlier it is at best $\Omega(a^2e)$ and at worst $O(a^3e)$. The unit of time used is the evaluation of a binary predicate on a pair of domain elements. We should not expect HAC to improve on the worst case performance of AC-3. Indeed, since it relies on a hierarchical organization of the domain one could perversely structure the domains in the worst possible way to ensure worst case behaviour worse than AC-3.

We first consider the time required to compute the hierarchical predicates A_{ij}^{kl} and S_{ij}^{kl} defined by the recursive equations (1) - (6). Computation of these predicates is a preprocessing step required by

HAC, if they are not already provided for an application. For each arc (i, j) we must compute A_{ij}^{kl} and S_{ij}^{kl} where $k, l = 0, 1, 2, \cdots m$. Consider that A_{ij}^{kl} is represented by a relation matrix, with $2^{m-k} \times 2^{m-l}$ entries. The total number of entries for A_{ij} is then

$$\sum_{k=0}^{m} \sum_{l=0}^{m} 2^{m-k} 2^{m-l}$$

$$=\sum_{p=0}^{m}\sum_{q=0}^{m}2^{p}2^{q}$$

$$= \left(\sum_{p=0}^{m} 2^{p}\right)^{2}$$

$$= (2^{m+1}-1)^2$$

Each entry requires 2 predicate evaluations to compute except the 2^{2m} entries in A_{00} which require 1. Similarly for S_{ij}^{kl} so for arc (i, j) the number of evaluations is:

$$2(2(2^{m+1}-1)^2-2^{2m})$$

$$= 2^{2m+4} - 2^{2m+1} - 2^{m+4} + 4$$

Since $a = 2^{m}$ this is $14a^{2}$. Let e be the number of edges in the constraint graph. There are 2e arcs and so the preprocessing computation requires $\theta(ea^{2})$, but this can be done once and for all for an application domain before any particular CSP is tackled.

The best case for HAC clearly occurs when the network is already strongly hierarchically arc consistent. In that case it merely has to check that condition which requires exactly 2e predicate evaluations of A_{ij}^{mm} between the root node of each domain tree and the root node of its neighbouring domain tree. So HAC is $\Omega(e)$.

Our analysis of the HAC worst case behaviour parallels the analysis in Mackworth and Freuder (1984) so it will not be spelled out in detail. Let d_i be the edge degree of vertex *i* in the constraint graph and let *n* be the number of vertices (variables). The worst case would occur when there is no solution but that fact is discovered in the slowest possible way. For each variable x_i REVISE-HAC can minimally replace one of the abstract labels by its two successors. When that occurs $(d_i -1)$ arcs are, at worst, added to HAC's arc queue Q. The domain size is the number of leaves in the domain tree, $a = 2^m$; therefore, that replacement can occur 2a-2 times since there are that many arcs in the domain tree.

 $\sim 14 \times 2^{2m}$

The number of arcs that are, in total, then removed from Q is the number of arcs originally on Q plus the number added to Q as a result of REVISE-HAC modifying a domain:

$$2e + \sum_{i=1}^{n} (2a-2)(d_i-1)$$

= 2e + (2a-2)(2e-n)

For each arc (i, j) the number of predicate evaluations is at worst the product of the current sizes of the two abstract label sets. Notice that there are a leaf vertices in the domain tree and a-1 interior nodes, for a total of (2a-1). Since no abstract label can be active at the same time as any of its descendants or ancestors the number of abstract labels active cannot exceed a. Accordingly the number of predicate evaluations is, at most,

$$a^{2}[2e + (2a-2)(2e-n)]$$

We may, without loss of generality, assume that $e \ge n-1$ (Mackworth and Freuder, 1984), and so the time complexity of HAC is $O(a^3e)$. Since the complexity of HAC is asymptotically $4a^3e$ compared to AC-3's $2a^3e$, the intuition that the worst case for HAC is worse than the worst case for AC-3 is confirmed and quantified: it may be twice as slow. Another way to approach this is to realize that we have essentially doubled the domain size from a to (2a-1) by adding the interior nodes so the number of possible deletions from the domain has doubled. However, since only a labels can be active at once the number of predicate evaluations is still only a^2 (not $(2a)^2 = 4a^2$) to test consistency at any iteration and so it is only twice as slow, not eight times! Notice that of the a active labels (a-1) each require up to a predicate evaluations of A_{ij} and the label that is deleted or replaced by its two successors requires up to 4a: A_{ij} and S_{ij} on the label itself and A_{ij} on its two successors. Since we assume $a \gg 1$ we have counted that as a^2 evaluations.

A more reasonable analysis of HAC would consider those applications in which the domains are appropriately structured. A way to characterize this is to require that there is only one abstract label active in each node's domain at anytime, that is, $|\Delta_i| \leq 1$. Intuitively, one can think then of the variable's domain being progressively refined and reduced by the evidence of its related neighbouring variables. The specialization hierarchy is then being used as a true discrimination tree. If this is the case then a similar analysis proceeds as follows. If REVISE-HAC returns true on (i, j) it has minimally replaced an abstract label by its successor. That can occur $m = \log_2 a$ times for that domain. Each time it occurs it adds $(d_i - 1)$ arcs to Q. The total number of arcs removed from Q is

$$2e + \sum_{i=1}^{n} (d_i - 1)\log a$$

$$= 2e + (2e - n)\log a$$

For each arc removed an application of REVISE-HAC is needed so the number of calls to REVISE-HAC is $2e + (2e - n)\log a$. We distinguish now between the successful calls to REVISE-HAC, on which a domain revision occurs and REVISE-HAC returns true, and the unsuccessful calls on which no change occurs and REVISE-HAC returns false. On the successful calls, REVISE-HAC tests A_{ij} on the single label in Δ_i and the label in Δ_j . That fails. S_{ij} succeeds. The label in Δ_i is replaced by its two successors: on one of them A_{ij} succeeds and on the other A_{ij} fails and S_{ij} fails. In all, 5 predicate evaluations are required. On the unsuccessful calls, only one evaluation of A_{ij} is required. The number of successful calls to REVISE-HAC is simply the number of possible deletions in a domain $(\log a)$ times the number of domains (n). The number of unsuccessful calls to REVISE-HAC is the number of calls, $2e + (2e - n)\log a$, minus the number of successful calls, $n \log a$. So the number of predicate evaluations is:

$$5(n \log a) + 1[2e + (2e - n)\log a - n \log a]$$

 $= 2e + (2e+3n)\log a$

-32-

And so, the worst case complexity of HAC under the specified condition is $O((e + \frac{3}{2}n)\log a)$, a remarkable improvement over AC-3's $O(a^3e)$.

7. Applications.

HAC has been implemented and used in Mapsee3 (Mulder, 1985), a schema-based system for interpreting hand drawn sketch maps. A brief note here on how it is used should be useful. Schema instances represent scene objects and correspond to what we have called variables here. As a schema instance acquires more evidence as to its nature by acquiring a new component, for example, it can specialize its own interpretation; this action corresponds to moving down the domain tree. Moreover, instances that it is already related to may then be further specialized and so on. A geographical system (Geo-system) has the specialization hierarchy shown in Figure 2(a) while a shoreline (Shore) has the specialization hierarchy of Figure 2(b).

Figure 2.

(a) Geo-system specialization hierarchy(b) Shore specialization hierarchy

Suppose a Geo-system completely surrounds a closed Shore in the map then we have the relation P_{ij} shown in Table 1.

Table 1

P_{ij}	Lakeshore	Coastline
Island	1	0
Mainland	1	0
Lake	0	1
Ocean	0	1

Table 1: P_{ij} for Geo-system Surrounds Shore

In other words either the Geo-system is an Island or a Mainland and the Shore a Lakeshore or the Geo-system is a Lake or an Ocean and the Shore a Coastline. From this relation we can compute the hierarchical predicates A_{ij}^{kl} and S_{ij}^{kl} using equations (1) - (6). They are shown in Table 2. (Note that $S_{ij}^{00} = A_{ij}^{00}$).

Τ	a	Ы	le	2

A_{ij}^{00}	Lakeshore	Coastline
Island	1	0
Mainland	1	0
Lake	0	1
Ocean	0	1

$A_{ij}^{\ \ 10}$	Lakeshore	Coastline
Landmass	1	0
Waterbody	0	1

$S_{ij}^{\ 10}$	Lakeshore	Coastline
Landmass	1	0
Waterbody	0	1

A_{ij}^{11}	Shore	
Landmass	1	
Waterbody	1	

S_{ij}^{11}	Shore
Landmass	1
Waterbody	1

A_{ij}^{20}	Lakeshore	Coastline	
Geo-system	0	0	

S_{ij}^{20}	Lakeshore	Coastline	
Geo-system	1	1	

A_{ij}^{21}	Shore	
Geo-system	0	

S_{ij}^{21}	Shore	
Geo-system	1	

Table 2: A_{ij} and S_{ij} for Geo-system Surrounded by Shore

Experimentally, for this application, Mulder (1985) has found that HAC is more efficient than AC-3. HAC is faster than AC-3 in Mapsee3 by a factor of about 2, although here the domains are still very small: a varies from 2 to 8. Mulder also reports experimental evidence that the number of iterations does depend linearly on the number of constraints.

For reasons discussed earlier we expect HAC to be most useful when the domains can be naturally described hierarchically; that is, when the interior nodes of the domain tree are natural kinds. There must be non-trivial relationships between the total set of elements represented at an internal node of one domain tree and the total set of elements at an internal node of the neighbouring domain tree. Moreover, we expect the advantages of HAC to be more fully realized for very large domains.

The original edge labelling paradigm in which arc consistency was invented (Waltz, 1972) is an example of such an application. Waltz essentially used the sets of possible corners as the variable domains with the edge type being the predicates. Interchanging the role of the corners and the edges so the variable domains are the edge types and the set of corners the predicates one can structure the very large number of edge types (1532) hierarchically (Mackworth, 1977b) and use HAC.

8. Conclusions

An hierarchical arc consistency algorithm for constraint satisfaction problems, HAC, has been described that exploits the internal structuring of domain values into a hierarchy of subdomains. Complexity results show that the algorithm has demonstrably improved be \uparrow and worst case performance if the domains obey certain constraints. In that case HAC is at best $\Omega(e)$ and at worst $O((e + \frac{3}{2}n)\log a)$ compared to $\Omega(a^2e)$ and $O(a^3e)$ for the previously best known algorithm. Experimental results from the use of the algorithm in a computational vision system, Mapsee3, are consistent with our analysis. 9. Acknowledgements
